

Package ‘ROct’

May 15, 2015

Type Package

Title Time-dependent ROC curve estimators and expected utility

Version 0.9.1

Date 2015-05-15

Author Y. Foucher, E. Dantan, P. Tessier and M. Lorent

Maintainer Y. Foucher <Yohann.Foucher@univ-nantes.fr>

Description This package contains functions in order to estimate time-dependent ROC with right-censored data. More precisely, two functions concern the estimation of ROC curves defined by Heagerty, Lumley and Pepe (Biometrics, 2000). The two other functions concern their adaptation for studying the capacity of a marker to predict the excess of mortality of a specific population compared to the general population (same age, gender and calendar year). This last part is based on additive relative survival models and the work of Pohar-Perme (Biometrics, 2011). In addition, we propose a function for optimal cut-off estimation for medical decision making by maximizing time-dependent expected utility function.

ROct-package

*Time-dependent ROC curves estimation***Description**

Compute time-dependent ROC curve and expected utility for medical decision making.

Details

Package:	ROct
Type:	Package
Version:	0.9.1
Date:	2015-05-15
License:	GPL (>=2)
LazyLoad:	yes

Several functions are available:

allcause.ROct	This function allows the estimation of usual time-dependent ROC curve.
net.ROct	This function allows the estimation of net time-dependent ROC curve.
e.utility	The expected utility theory allows the estimation of optimal cut-of for medical decision making.

allcause.ROct	<i>Time-dependent ROC curves with right censored data</i>
---------------	---

Description

This function performs the characteristics of a time-dependent ROC curve based on k-nearest neighbor's (knn) estimator or only based on the Kaplan and Meier estimator.

Usage

```
allcause.ROct(times, failures, variable, pro.time, cut.off, estimator, lambda)
```

Arguments

times	A numeric vector with the follow up times.
failures	A numeric vector with the event indicator (0=right censored, 1=event).
variable	A numeric vector with the prognostic variable. This variable is collected at the baseline.
pro.time	The value of prognostic time represents the maximum delay for which the capacity of the variable is evaluated. The same unit than the one used in the argument time.
cut.off	The cut-off values of the variable used to define the possible binary tests.
estimator	Three possible estimators can be used: 'kaplan-meier', 'akritas' or 'naive'. The naive estimator is selected by default.
lambda	This is the proportion of the nearest neighbors. The estimation will be based on $2 \times \lambda$ (1 lambda on the left and 1 lambda on the right) of the total sample size. This parameter will only be used in the k-nearest neighbor's estimation (estimator='akritas').

Details

This function computes time-dependent ROC curve with right-censoring data. It can use Akritas approach (nearest neighbor's estimation) for ensuring monotone increasing ROC curve, instead of the simple Kaplan-Meier estimator. This Akritas approach may be avoid if the sample size is large because of computing time. Both estimators were defined by Heagerty, Lumley and Pepe (Biometrics, 2000). A third alternative is the use of the naive estimator as explained by Blanche, Dartigues and Jacqmin-Gadda (2013). This estimator is less time-consuming compared to the Akritas approach.

Value

table	This data frame presents the sensitivities and specificities associated with the cut-off values. One can observe NA if the value cannot be computed.
auc	The area under the time-dependent ROC curve for a prognostic up to prognostic time.
missing	Number of deleted observations due to missing data.

```

dataDIVAT	<i>A sample of the DIVAT cohort in order to study the mortality of kidney transplant recipients.</i>
-----------	--

Description

A data frame with 4267 French kidney transplant recipients. The time-to-event is the time between the transplantation and the recipient death. This time can be right-censored. A vector of covariates is also collected at the transplantation.

Usage

```
data(dataDIVAT)
```

Format

A data frame with 4267 observations (rows) with the 8 following variables (columns).

ageR This numeric vector represents the age of the recipient (in years)

sexeR This numeric vector represents the gender of the recipient (1=men, 0=female)

year.tx This numeric vector represents the year of the transplantation

ante.diab This numeric vector represents the diabetes statute (1=yes, 0=no)

pra This numeric vector represents the pre-graft immunization using the panel reactive antibody (1=detectable, 0=undetectable)

ageD This numeric vector represents the age of the donor (in years)

death.time This numeric vector represents the follow up time in days (until death or censoring)

death This numeric vector represents the death indicator at the follow-up end (1=death, 0=alive)

Details

The immunology and nephrology department of the Nantes University hospital constituted a data bank with the monitoring of medical records for kidney and/or pancreas transplant recipients. The associated software is called DIVAT. Here is a sample of 4267 patients. The time-to-event is the time between the transplantation and the death of the recipient. This time can be right-censored. A vector of covariates, all measured at the transplantation, is also collected for each patient.

Source

URL: <http://www.divat.fr>.

Examples

```
data(dataDIVAT)
```

```
### a short summary of the recipient age at the transplantation  
summary(dataDIVAT$ageR)
```

```
### Kaplan and Meier estimation of the recipient survival  
plot(survfit(Surv(death.time/365.25, death) ~ 1, data = dataDIVAT),  
     xlab="Post transplantation time (in years)", ylab="Patient survival",  
     mark.time=FALSE)
```

dataKTFS

A sample of the DIVAT cohort in order to study the prognostic capacities of the Kidney Transplant Failure Score (KTFS).

Description

A data frame with 2169 French kidney transplant recipients. The time-to-event is the time between the transplantation and the return in dialysis. This time can be right-censored, especially at the time of the patient death with a functioning graft. The KTFS is a score proposed by Foucher et al. (2010) to stratify the recipients according to their risk of return in dialysis.

Usage

```
data(dataKTFS)
```

Format

A data frame with 2169 observations (rows) with the 3 following variables (columns).

time This numeric vector represents the follow up time in years (until return in dialysis or censoring)

failure This numeric vector represents the graft failure indicator at the follow-up end (1=return, 0=censoring)

score This numeric vector represents the KTFS values.

Details

The immunology and nephrology department of the Nantes University hospital constituted a data bank with the monitoring of medical records for kidney and/or pancreas transplant recipients. The associated software is called DIVAT. Here is the training sample of 2169 patients used for the construction of the KTFS, a scoring system proposed by Foucher et al. (2010) in order to stratify patients according to their risk of return in dialysis. The KTFS is based on 8 parameters collected during the first year post transplantation. Patients with a KTFS value higher than 4.17 were considered at high-risk.

```

```
### a short summary of the recipient age at the transplantation
summary(dataKTFS$score)
```

```
### Kaplan and Meier estimation of the recipient survival
plot(survfit(Surv(time, failure) ~ I(score>4.17), data = dataKTFS),
```

```
xlab="Post transplantation time (in years)", ylab="Patient survival",
mark.time=FALSE, col=c(2,1), lty=c(2,1))
legend("bottomleft", c("Recipients in the high-risk group",
"Recipients in the low-risk group"), col=1:2, lty=1:2)
```

EUt

Optimal cut-off estimation of a prognostic variable

Description

This function allows the estimation of an optimal cut-off estimation for medical decision making from a prognostic marker by maximizing the expected utility.

Usage

```
EUt(times, failures, variable, pro.time, cut.off, estimator, lambda = NULL,
u.tn, u.fp, u.tp0, u.tp1, u.fn0, u.fn1, gain = 0, reference = "negative")
```

Arguments

times	A numeric vector with the follow up times.
failures	A numeric vector with the event indicator (0=right censored, 1=event).
variable	A numeric vector with the prognostic variable. This variable is collected at the baseline.
pro.time	The value of prognostic time represents the maximum delay for which the capacity of the variable is evaluated. The same unit than the one used in the argument time.
cut.off	The cut-off values of the variable used to define the possible binary tests.
estimator	Three possible estimators can be used: 'kaplan-meier', 'akritas' or 'naive'. The naive estimator is selected by default.
lambda	This is the proportion of the nearest neighbours. The estimation will be based on 2*lambda (1 lambda on the left and 1 lambda on the right) of the total sample size. This parameter will only be used in the k-nearest neighbour's estimation (estimator='akritas').
u.tn	The value of the utility related to a patient with a true negative test. This value should respect the 0-1 scale death-perfect health.
u.fp	The value of the utility related to a patient with a false positive test. This value should respect the 0-1 scale death-perfect health.
u.tp0	The value of the utility related to a patient with a true positive test before the failure occurs. This value should respect the 0-1 scale death-perfect health.
u.tp1	The value of the utility related to a patient with a true positive test after the failure occurs. This value should respect the 0-1 scale death-perfect health.
u.fn0	The value of the utility related to a patient with a false negative test before the failure occurs. This value should respect the 0-1 scale death-perfect health.
u.fn1	The value of the utility related to a patient with a false negative test after the failure occurs. This value should respect the 0-1 scale death-perfect health.

gain	A numeric vector with the expected percentages in the increase of the mean time-to-failure due to the novel therapy. The default value is 0. These values have to be between 0 and 100. The size of the vector have to be the same than the one of the argument "cut.off". It allows the possibility to consider a dependence between the cut-off value and the gain.
reference	The possible options are "negative" or "positive". That indicates the group of patients maintained with the reference (standard) care. For instance if "negative", patients with a negative test will received the reference care, while patients with a positive test will receive the novel therapy. The default value is "negative".

Details

This function computes the expected utility function for the cut-off defined by the user. The individual data may be right-censored. It can use Akritas approach (nearest neighbour's estimation) for ensuring monotone property of the corresponding function, instead of the simple Kaplan-Meier estimator. This Akritas approach may be avoid if the sample size is large because of computing time. Both estimators were defined by Heagerty, Lumley and Pepe (Biometrics, 2000). A third alternative is the use of the naive estimator as explained by Blanche, Dartigues and Jacqmin-Gadda (2013). This estimator is less time-consuming compared to the Akritas approach. The user have to define the utilities/qualities of life related to the possible health-states of the patients after the prognostic marker-based decision. A positive test is defined by a marker value higher than the cut-off: the patient is considered at risk of the failure before the prognostic time. The situation consists in the prescription of a novel therapy to avoid/delay the failure in high-risk patients, but with a decrease in the quality of life versus non-treated patients. For true positive and false negative test, we distinguish the quality of life before and after the failure, the quality of life being higher before than after.

Value

missing	Number of deleted observations due to missing data.
proba.table	This data frame is composed by 4 columns representing respectively the probabilities of true positive test (tp), false positive test (fp), true negative test (tn) and false negative test (fn). Each line corresponds to the cut-off values entered by the user.
qaly.table	This data frame is composed by 4 columns representing respectively the QALYs of true positive test (tp), false positive test (fp), true negative test (tn) and false negative test (fn). Each line corresponds to the cut-off values entered by the user.
eu.table	This data frame returns the expected utilities associated with the cut-off values entered by the user.
eu.all	The expected utility if all patients are treated (the cut-off is the minimum of the prognostic variable).
eu.no	The expected utility if no patient is treated (the cut-off is the maximum of the prognostic variable).
results	This vector contains three values. The first one is (estimation) is the cut-off that maximizes the expected utility of the medical decision. If this value corresponds to the minimum or the maximum of the prognostic variable, all the patients or no patient should respectively be treated. The second one (eu) corresponds to the maximum expected utility associated with the previous cut-off value. The third one (gain) corresponds to the gain entered by the user for this estimated cut-off.

# cut-off values definition (choose more values in practice)

ktfs.cut <- quantile(dataKTFS$score, probs=seq(0.1, 0.9, by=0.1), na.rm=TRUE)

# the corresponding expected utility function for a prognostic
# up to 8 years post-transplantation

estim.naive <- EUT(dataKTFS$time, dataKTFS$failure, dataKTFS$score,
  pro.time=8, cut.off=ktfs.cut, estimator="naive", lambda=NULL, u.tn=0.81,
  u.fp=0.81*0.99, u.tp0=0.81*0.99, u.tp1=0.53, u.fn0=0.81, u.fn1=0.53,
  gain=0.5)

plot(estim.naive$eu.table$cut.off, estim.naive$eu.table$utility, type="l",
  xlab="Cut-off values", ylab="Expected utility", col=1, lty=1)
```

fr.ratetable

Expected mortality rates of the general French population.

Description

An object of class ratetable for the expected mortality of the French population. It is a array with three dimensions: age, sex and year.

Usage

```
data(fr.ratetable)
```

Format

The format is "ratetable". The attributes are:

dim A numeric vector with the length of each dimension.

dimnames A list of vectors with the names of each variable of the three dimensions.

dimid A character vector with the identification of the dimensions: age, year and sex.

factor A vector of indicators=1 if the corresponding dimension do not vary according to the time. Only the sex is associated to 1.

cutpoints A list of the thresholds to identify the mortality rates according to the time-varying dimensions (NULL for sex).

class The class of the object: ratetable.

Details

The organization of a ratetable object is described in details by Therneau (1999) and Pohar (2006).

Source

The original data and updates can be downloaded from the Human Life-Table Database (HMD, The Human Mortality Database). URL: <http://www.mortality.org/>

Examples

```
data(fr.ratetable)

is.ratetable(fr.ratetable)
```

net.ROct

Net time-dependent ROC curves with right censored data

Description

This function performs the characteristics of a net time-dependent ROC curve based on k-nearest neighbor's (knn) estimator or only based on the Pohar-Perme estimator (Pohar, 2012).

Usage

```
net.ROct(times, failures, variable, p.age, p.sex, p.year,
  rate.table, pro.time, cut.off, knn=FALSE,
  lambda=NULL)
```

Arguments

times	A numeric vector with the follow up times.
failures	A numeric vector with the event indicator (0=right censored, 1=event).
variable	A numeric vector with the prognostic variable. This variable is collected at the baseline.
p.age	A numeric vector with the age of the individuals at the baseline (in days).

p.sex	A character vector with the gender the individuals ('male' or 'female').
p.year	A numeric vector with the calendar year at the baseline (number of days from the January 1, 1960).
rate.table	A ratetable object with the expected mortality rates by age, sex, and cohort year. The same units used in p.age, p.sex, p.year
pro.time	The value of prognostic time represents the maximum delay for which the capacity of the variable is evaluated. The same unit than the one used in the argument time.
cut.off	The cut-off values of the variable used to define the possible binary tests.
knn	A logical value indicating whether k-nearest neighbor's estimator should be used.
lambda	This is the proportion of the nearest neighbors. The estimation will be based on 2*lambda (1 lambda on the left and 1 lambda on the right) of the total sample size.

Details

This function computes net time-dependent ROC curve with right-censoring data using estimator defined by Pohar-Perm et al. (2011) and the k-nearest neighbor's (knn) estimator. The aim is to evaluate the capacity of a variable (measured at the baseline) to predict the excess of mortality of a studied population compared to the general population mortality. Using the knn estimator ensures a monotone and increasing ROC curve, but the computation time may be long. This approach may thus be avoided if the sample size is large because of computing time.

Value

table	This data frame presents the sensitivities and specificities associated with the cut-off values. One can observe NA if the value cannot be computed.
auc	The area under the time-dependent ROC curve for a prognostic up to prognostic time.
missing	Number of deleted observations due to missing data.
warning	This message indicates possible difficulties in the computation of the net ROC curve, for instance if the net survival was not lower or equal 1 to 1 for particular cut-off values or times.

```

rein.ratetable

Expected mortality of French patients with End Stage Kidney Disease (ESKD) in dialysis and registrited previously on waiting list for renal transplantation

Description

An object of the class `ratetable` which contains the expected mortality of French patients with End Stage Kidney Disease (ESKD) in dialysis and registered previously on waiting list for renal transplantation. It is an array with two dimensions: the time since the registry on waiting list and the patient profile at this baseline.

Usage

```
data(rein.ratetable)
```

Format

The format is "ratetable". The attributes are:

`dim` A numeric vector with the length of each dimension.

`dimnames` A list of vectors with the names of each variable of both dimensions (see details for modalities of profile).

`dimid` A character vector with the identification of the dimensions: time, profile.

`factor` A vector of indicators=1 if the corresponding dimension do not vary according to the time. The profile is associated to 1.

`cutpoints` A list of the thresholds to identify the mortality rates according to the time-varying dimensions (NULL for profile).

`class` The class of the object: `ratetable`.

Details

The organization of a `ratetable` object is described in details by Therneau (1999) and Pohar (2006). We have estimated these data by using the renal epidemiology and information network (REIN). A competing risk model was performed in order to deal with the loss of follow-up to the transplantation. The profile represents the concatenation of the significant binary variables associated with the mortality on waiting list. In order to obtain the same variable in your database, we have to concatenate the following values in the same order. These values are collected at the registration date:

- a. 1 if the patient is male and 0 if female.
- b. 1 if the time between the first dialysis and the registration is higher than 1 year and 0 otherwise.
- c. 1 if hemodialysis and 0 if peritoneal dialysis.
- d. 1 if the patient is diabetic and 0 otherwise.
- e. 1 if the patient had history of cardiac failure diabetic and 0 otherwise.
- f. 1 if the patient had history of vascular failure diabetic and 0 otherwise.
- g. 1 if the patient had history of cancer and 0 otherwise.
- h. 1 if the age of the patients is in between 40 and 60 years and 0 otherwise.
- i. 1 if the age of the patients is higher than 60 years and 0 otherwise.
- j. 1 if the calendar year at registration is strictly higher than 2007 and 0
